## Assignment #9

Due: Wednesday, April 29

TA: Kristin Beck

Room: 26-223 or 26-228a Email: kbeck@mit.edu

Office Hours: April 24th and 27th, 9am-10am and by arrangement

Consider the following questions for sodium. Plug in numbers after obtaining an analytical expression.

Na oven temperature T=600Knatural line width  $\gamma=2\pi\times$  10 MHz Zeeman splitting 1.4 MHz/gauss wavelength  $\lambda=2\pi/k=589$  nm

## 1. A Zeeman Slower

If you want to slow an atomic beam efficiently, you have to compensate for the changing Doppler shift  $(\vec{k} \cdot \vec{v})$  during the deceleration. This can be done by sweeping the frequency of the slowing beam, i.e., chirping. Another method of producing a continuous beam of cold atoms is Zeeman slowing.

A well collimated beam of atoms originates from an oven with a temperature T. The beam propagates along a distance L with a longitudinal magnetic field B(x) (0 < x < L). A laser beam of intensity I is counter propagating. Its frequency is detuned by  $\delta$  ( $\delta \equiv \omega - \omega_0$ ) from the transition frequency at B = 0.

a) Calculate the maximum deceleration  $a_{max}$  you can achieve. Assume you could choose an arbitrarily large laser intensity.

Assume you want to slow down atoms with speeds lower than the peak (most probable) velocity  $v_{peak}$  of the thermal distribution to a stand still (v=0) using the constant deceleration  $fa_{max}$ . (0 < f < 1) The Zeeman effect shifts the resonance  $\omega_0 \to \omega_0 + g\mu_B B(x)$  (where  $g\mu_B = (2\pi)1.4$  MHz/gauss, in this case).

b) Calculate the spatial dependence of the magnetic field B(x) and the length L of the slower as a function of f.

Atoms slow down by scattering photons, and the way in which this scattering happens affects the final momentum distribution. Assume three different models for spontaneous emission: (i) Photons are emitted along the  $+/-\hat{x}$  direction, (ii) isotropic emission, or (iii) emission in a dipole pattern.

c) What is the momentum diffusion constant  $\mathcal{D}$  for the (longitudinal) x-component of the momentum in these three different models (i-iii) of spontaneous emission for a photon scattering rate  $\Gamma_s$ ?

## 2. Slowing an atom with off-resonant light

Assume you want to slow an atom of velocity  $v_{peak}$  with a counter propagating laser beam that is on resonance with the atom at rest. (Use the same  $v_{peak}$  as in Problem 1, and  $I = 5I_{sat}$ .)

- a) How long would it take?
- b) How far would the atom travel?

(Hint: Think about integrating the equation of motion)

- c) How does this compare to the Zeeman slower we considered in Problem 1?
- 3. **Density Limit in a MOT**. In a 3-D magneto-optical trap, the density of the trapped atoms is limited by a net outward radiation pressure which opposes the trapping force. We can divide the density-dependent photon-pressure force into two parts: (i) a repulsive 'radiation trapping force' due to atoms absorbing photons scattered from other atoms in the trap and (ii) an attractive 'attenuation force' caused by atoms at the side of the cloud attenuating the laser beams, creating an intensity imbalance which leads to an inward force.
  - (a) Show that the radiation trapping force obeys the equation

$$\nabla \cdot \mathbf{F}_R = \frac{6\sigma_L \sigma_R In}{c},$$

where **I** is the intensity of one of the trapping laser beams, n is the number density of atoms in the cloud,  $\sigma_L$  is the cross-section for absorption of the laser beam, and  $\sigma_R$  is the cross-section for absorption of the scattered light. (**Hint**: Find the magnitude of the force between two atoms separated by a distance d, where one atom re-radiates a laser photon and the second atom absorbs it. Now, since this is an inverse-square force, you can use Gauss' law to find  $\nabla \cdot \mathbf{F}_R$ . Assume that photons are only scattered twice.)

(b) The attenuation force may be obtained simply by replacing  $\sigma_R$  with  $-\sigma_L$ , so that

$$\nabla \cdot \mathbf{F}_A = -\frac{6\sigma_L^2 In}{c}.$$

Explain why this is so.

- (c) The total force is the sum of  $\mathbf{F}_R$ ,  $\mathbf{F}_A$ , and the trapping force  $\mathbf{F}_T = -\kappa \mathbf{r}$ , where  $\kappa$  is the spring constant of the trap. For stability we require that the total force is attractive,  $\nabla \cdot \mathbf{F}_{total} < 0$ . Find the maximum density of the trapped cloud at a given  $\kappa$  from the condition  $\nabla \cdot \mathbf{F}_{total} = 0$ .
- (d) Give a qualitative argument for whether we expect  $\sigma_R = \sigma_L, \sigma_R > \sigma_L$ , or  $\sigma_R < \sigma_L$ . ( **Hint**: sketch the absorption and emission spectra for an atom in a strong laser field with a red detuning.)
- (e) Suppose that some of the atoms can be put into a 'dark state', so that only a fraction f of the atoms absorb the trapping light. How do  $F_R$ ,  $F_A$  and  $F_T$  vary with f? What happens to the limiting density  $n_{max}$ ? This is the concept of the Dark SPOT trap (PRL **70**, 2253 (1993)).
